Abstract

Objective: To assess the epidemiological evidence on diet and cancer and make public health recommendations.

Design: Review of published studies, concentrating on recent systematic reviews, meta-analyses and large prospective studies.

Conclusions and recommendations: Overweight/obesity increases the risk for cancers of the oesophagus (adenocarcinoma), colorectum, breast (postmenopausal), endometrium and kidney; body weight should be maintained in the body mass index range of 18.5–25 kg/m², and weight gain in adulthood avoided. Alcohol causes cancers of the oral cavity, pharynx, oesophagus and liver, and a small increase in the risk for breast cancer; if consumed, alcohol intake should not exceed 2 units/d. Aflatoxin in foods causes liver cancer, although its importance in the absence of hepatitis virus infections is not clear; exposure to aflatoxin in foods should be minimised. Chinese-style salted fish increases the risk for nasopharyngeal cancer, particularly if eaten during childhood, and should be eaten only in moderation. Fruits and vegetables probably reduce the risk for cancers of the oral cavity, oesophagus, stomach and colorectum, and diets should include at least 400 g/d of total fruits and vegetables. Preserved meat and red meat probably increase the risk for colorectal cancer; if eaten, consumption of these foods should be moderate. Salt preserved foods and high salt intake probably increase the risk for stomach cancer; overall consumption of salt preserved foods and salt should be moderate. Very hot drinks and foods probably increase the risk for cancers of the oral cavity, pharynx and oesophagus; drinks and foods should not be consumed when they are scalding hot. Physical activity, the main determinant of energy expenditure, reduces the risk for colorectal cancer and probably reduces the risk for breast cancer; regular physical activity should be taken.

Review

Dietary factors have been thought to account for about 30% of cancers in Western countries¹, making diet second only to tobacco as a preventable cause of cancer. The contribution of diet to cancer risk in developing countries has been considered to be lower, perhaps around 20%². Unravelling the effects of diet on cancer risk is, therefore, of great public health importance, but research to date has uncovered few definite effects and left frustratingly large areas of uncertainty.

In this paper, we summarise our view of the current state of knowledge on diet and cancer. This paper is not a systematic review of diet and cancer. Other organisations have recently published detailed reviews of this subject, in particular the World Cancer Research Fund/American Institute for Cancer Research³, and the Department of Health in the UK⁴. These publications provide good reviews of research published up until the mid 1990s; we

have, therefore, based our review on the material summarised in these reports and on more recent studies, giving particular credence to the results of large prospective studies and to the few results from randomised controlled trials. We start by briefly discussing the types of evidence available for formulating and testing hypotheses.

International comparisons, migrants and time trends

Many of the prominent hypotheses for effects of diet on cancer risk have been derived from examination of the associations between dietary patterns and cancer rates in different populations around the world. It was noted in the 1970s that developed Western countries have diets high in animal products, fat and sugar, and high rates of cancers of the colorectum, breast and prostate. In contrast,

developing countries typically have diets based on one or two starchy staple foods, low intakes of animal products, fat and sugar, low rates of these 'Western' cancers, and sometimes high rates of other types of cancer such as cancers of the oesophagus, stomach and liver⁵. Other studies have shown that cancer rates often change in populations which migrate from one country to another, and change over time within countries. For example, the formerly low rates of colorectal cancer among Japanese people have increased both on migration to the USA and, more recently, with the increasing Westernisation of the diet in Japan⁶. As discussed below, some of the main hypotheses that were derived from these ecological observations have not been supported by the results of detailed studies of the diets of individuals. However, the international variations in diet and cancer rates continue to suggest that diet is an important risk factor for many common cancers, and therefore that cancer may be partly preventable by dietary changes.

Figure 1 shows estimated incidence rates for the most common cancers world-wide in 2000⁷. Lung cancer is the most common cancer in the world, and the most common cancer among men in both developed and developing countries, whereas breast cancer is the most common cancer among women. The archetypal Western cancers are those of the colorectum, breast and prostate. Westernisation encompasses many changes in diet and lifestyle, including increased consumption of meat, dairy

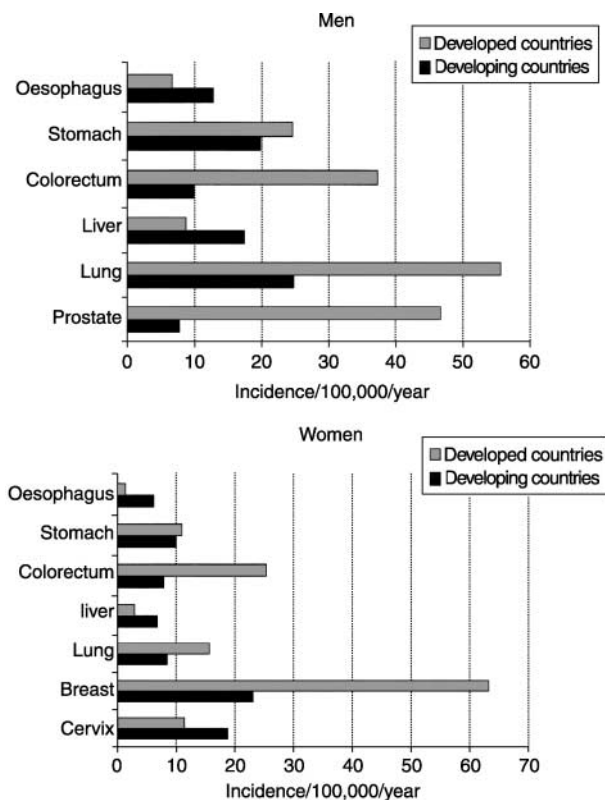

Fig. 1 Age-adjusted incidence rates of common cancers among men and women in developed and developing countries

products, sugar and other refined carbohydrates, and reduced intake of relatively unrefined starchy staple foods. In terms of nutrients, Western diets are characterised by adequate or excessive energy intake, together with high intakes of protein and fat, whereas micronutrient deficiency (i.e. deficiency of vitamins or trace minerals) is much more common in developing countries. Thus, the search for the nutritional causes of the typical Western cancers has focussed mainly on excess consumption of macronutrients, whereas the search for the nutritional causes of the typical cancers of developing countries has focussed on deficient intake of micronutrients.

Case-control studies

During the last 30 years, hundreds of studies have been published that have examined the association between the diets of individuals and their risk for developing cancer. Most of the earlier studies used a case-control design, in which people who already have cancer are asked what they used to eat before they were diagnosed with cancer, and their diets are compared with those reported by people without cancer (controls). These case-control studies are useful for searching for possible dietary effects, but cannot be relied on to establish moderate dietary associations because they are susceptible to both recall and selection biases: people with cancer may recall their diet differently from healthy people, and healthy controls are rarely fully representative of the base population and may report a relatively 'healthy' diet^{8,9}. The impact of these biases varies between studies, especially in relation to the participation rate among eligible controls, but in general relative risks in case-control studies of up to at least 1.3 may reflect bias rather than a true association.

Prospective studies

In prospective studies, dietary intakes are measured at recruitment and people are followed-up for cancer incidence, then the cancer incidence rates are compared between groups with different diets at baseline. This design eliminates the recall and selection biases to which case-control studies are susceptible, but other factors such as measurement error and confounding must be considered when interpreting the results of prospective studies (as well as case-control studies) of diet and cancer. Another limitation of most prospective studies is that the baseline dietary intake is measured at one point during adult life, which may not be the most relevant period in relation to the development of cancer over many years.

Interpretation of observational studies

Large prospective studies can establish whether or not there is any association between reported diet and cancer risk within the population studied. The main factors that need to be considered when interpreting results from such studies are measurement error and confounding.

Measurement error

Epidemiological studies generally use a relatively short and simple dietary questionnaire. The validity of such questionnaires has been extensively investigated, and while it is clear that current assessment methods are moderately precise and can detect some associations of diet with disease risk, it is also possible that the measurement error is sometimes large enough to obscure some potentially important associations of diet with cancer risk. A further problem is that there are often strong correlations between different foods and nutrients, making it hard to attribute associations with risk to particular dietary factors, especially when the precision of the measurements is variable.

Body mass index (the weight in kilograms divided by the square of the height in metres: kg/m²) and alcohol present special cases. Body mass index is not diet *per se*, but is determined by the balance of energy intake and energy expenditure; body mass index therefore serves as an indicator of chronic energy balance, and can be measured much more accurately and precisely in epidemiological studies than either energy intake or energy expenditure. Alcohol is not always included under the term diet, but alcoholic drinks do contribute a significant supply of energy and some nutrients in many populations. Although estimates of alcohol intake commonly suffer from underreporting, they generally rank individuals much more precisely than estimates of intakes of other foods and nutrients.

Confounding

Observed associations of dietary factors with cancer risk can be confounded by other risk factors for cancer, such as smoking and physical activity, which are associated with dietary habits. In theory, confounding can be allowed for by statistical adjustments, but in practice this adjustment is never perfect because the non-dietary risk factors themselves are measured with some error. The possibility that apparent dietary associations with cancer risk are confounded by other risk factors, therefore, needs to be examined very carefully. Allowing for confounding is extremely important for cancers such as lung cancer, where smoking causes a very large increase in risk and is known to be associated with diet. The relationship between diet and other cancers needs to take into account potential confounding factors, such as *Helicobacter pylori* for stomach cancer, physical activity for colorectal cancer, and human papillomavirus for cervical cancer (see below).

Randomised controlled trials

Randomised controlled trials eliminate both the biases and the confounding which can affect observational studies and the results can, therefore, be confidently interpreted in terms of cause and effect. Within the field of diet and cancer, however, trials are limited by the difficulty of randomising at the level of foods, and by the constraints

that only a small number of nutritional factors can be tested in each trial, usually for a short period. The results of the few large trials that have been completed are important, but where trials do not show an effect it remains possible that an effect would have been seen at a different dose, at a different time in life, or if the duration of the trial had been longer. Another point which should be considered when interpreting the results from randomised controlled trials is the possibility that the effect of a dietary component on cancer risk may differ according to the characteristics of the population studied; for example, the effects of a multinutrient supplement could be more marked in a population with a low dietary intake of micronutrients than in a population with a high dietary intake of micronutrients.

Within the field of diet and cancer, randomised controlled trials are most suitable for testing hypotheses for protective effects of specific micronutrients. An extensive review of these hypotheses and of the design and interpretation of such trials is given in the first IARC Handbook of Cancer Prevention¹⁰.

Review of the role of diet in the aetiology of the major cancers

Cancers of the oral cavity, pharynx and oesophagus

Cancers of the oral cavity, pharynx and oesophagus were estimated to account for 867,000 cases and 582,000 deaths in 2000¹¹. Incidence rates of these cancers vary widely between populations; for example, oesophageal cancer is over a hundred times more common in parts of Central Asia, China and Southern Africa than in most parts of Europe, North America and West Africa⁷. In developed countries, the main risk factors are alcohol and tobacco, and up to 75% of these cancers are attributable to these two lifestyle factors⁶. The mechanism of the effect of alcohol on these cancers is not known, but may involve direct effects on the epithelium¹². Overweight/obesity is an established risk factor specifically for adenocarcinoma (but not squamous cell carcinoma) of the oesophagus^{13–15}. In developing countries, around 60% of cancers of the oral cavity, pharynx and oesophagus are thought to be due to micronutrient deficiencies related to a restricted diet that is low in fruits and vegetables and animal products^{3,16}; it should be noted, however, that the evidence for a protective effect of fruits and vegetables is largely derived from case-control studies and there are few data yet from prospective studies¹⁷. The relative roles of various micronutrients are not yet clear, but deficiencies of riboflavin, folate, vitamin C and zinc may all be important^{3,16}. There is also consistent evidence that consuming drinks and foods at a very high temperature increases the risk for these cancers¹⁸. The results of trials in Linxian, China, aimed at reducing oesophageal cancer

rates with micronutrient supplements, have been promising but not definitive^{19,20}.

Nasopharyngeal cancer

This is particularly common in Southeast Asia⁷, and has been consistently associated with a high intake of Chinese-style salted fish, especially during early childhood^{21,22}, as well as with infection with the Epstein–Barr virus²³. Chinese-style salted fish is a special product which is usually softened by partial decomposition before or during salting; other types of salted fish have been studied and not found to be convincingly associated with the risk for developing nasopharyngeal cancer²².

Stomach cancer

Stomach cancer was estimated to account for 876,000 cases and 647,000 deaths in 2000¹¹. Until about 20 years ago stomach cancer was the most common cancer in the world, but mortality rates have been falling in all Western countries²⁴ and stomach cancer is now much more common in Asia than in Europe or North America⁷. Infection with the bacterium *H. pylori* is an established risk factor, but not a sufficient cause, for the development of stomach cancer²⁵. Diet is also thought to be important in the aetiology of this disease, and dietary changes are implicated in the recent decline in stomach cancer incidence and mortality rates in many countries. Substantial evidence, mainly from case-control studies, suggests that risk is increased by high intakes of some traditionally preserved salted foods, especially meats and pickles, and with salt *per se*, and that risk is decreased by high intakes of fruits and vegetables²⁶, perhaps due to their vitamin C content. However, evidence from prospective studies does not clearly support a protective effect for fruits and vegetables^{27,28}. The introduction of refrigeration has also been associated with decreased risk, probably through reducing intakes of salted foods and facilitating year-round fruit and vegetable availability³.

The results of micronutrient supplementation trials in developing countries have been encouraging but not definitive. In Linxian, China, combined supplementation with β -carotene, selenium and α -tocopherol resulted in a significant reduction in stomach cancer mortality, but no significant benefit was obtained from vitamin C¹⁹. A recent trial in Colombia showed increased regression of precancerous gastric dysplasia both in subjects given β -carotene and in subjects given vitamin C²⁹.

Further prospective data are needed, in particular to examine whether some of the dietary associations may be partly confounded by *H. pylori* infection and whether dietary factors may modify the association of *H. pylori* with risk.

Colorectal cancer

Colorectal cancer is the third most common cancer in the world⁷ and was estimated to account for 945,000 cases and

492,000 deaths in 2000¹¹. Incidence rates are approximately 10-fold higher in developed than in developing countries⁷. It has been suggested that diet-related factors may account for up to 80% of the between-country differences in rates³⁰. The best established dietary-related risk factor is overweight/obesity¹⁵. Alcohol probably causes a small increase in risk³. Adult height, which is partly determined by the adequacy of nutrition in childhood and adolescence, is weakly associated with increased risk, and physical activity has been consistently associated with a reduced risk^{15,31}. These factors together, however, do not explain the large variation between populations, and there is almost universal agreement that some aspects of a Western diet are a major determinant of risk.

Meat

International correlation studies show a strong association between per capita consumption of meat and colorectal cancer mortality⁵, and several mechanisms have been proposed through which meat may increase cancer risk. Mutagenic heterocyclic amines and polycyclic aromatic hydrocarbons can be formed during the cooking of meat at high temperatures^{32,33}, and nitrites and their related compounds found in smoked, salted and some processed meat products may be converted to carcinogenic *N*-nitroso compounds in the colon³⁴. In addition, high iron levels in the colon may increase the formation of mutagenic free radicals³⁵. The results of observational studies of meat and colorectal cancer have varied³; a recent systematic review concluded that preserved meat is associated with an increased risk for colorectal cancer but that fresh meat is not³⁶ and most studies have not observed positive associations with poultry or fish³. However, mortality rates for colorectal cancer are similar in Western vegetarians and comparable non-vegetarians³⁷. Overall, the evidence is not conclusive but suggests that high consumption of preserved and red meat probably increases the risk for colorectal cancer.

Fat

As with meat, international correlation studies show a strong association between per capita consumption of fat and colorectal cancer mortality⁵. Possible mechanisms proposed to explain such an association are that a high fat intake may increase the levels of cytotoxic free fatty acids or secondary bile acids in the lumen of the large intestine. However, the results of observational studies of fat and colorectal cancer have, overall, not been supportive of an association with fat intake, especially after adjusting for total energy intake^{3,38}.

Fruits, vegetables and fibre

Burkitt³⁹ suggested that the low rates of colorectal cancer in Africa were due to the high consumption of dietary fibre, and there are several plausible mechanisms for a protective effect. Fibre increases stool bulk and speeds the

transit of food through the colon, thus diluting the gut contents and perhaps reducing the absorption of carcinogens by the colonic mucosa⁴⁰. Fermentation of fibre (and resistant starch) in the large intestine produces short chain fatty acids such as butyrate, which may protect against colorectal cancer through the ability to promote differentiation, induce apoptosis and/or inhibit the production of secondary bile acids by reducing luminal pH^{41,42}. Many case-control studies of colorectal cancer have observed moderately lower risk in association with high consumption of dietary fibre, and/or fruits and vegetables^{43,44}, but the results of recent large prospective studies have been inconsistent⁴⁵⁻⁴⁷. Furthermore, results from randomised controlled trials have not shown that intervention over a 3-4 year period with supplemental fibre or a diet low in fat and high in fibre and fruits and vegetables can reduce the recurrence of colorectal adenomas⁴⁸⁻⁵⁰. It is possible that some of the inconsistencies are due to differences between studies in the types of fibre eaten and in the methods for classifying fibre in food tables. Other possibilities are that the association with fruits and vegetables is principally due to an increase in risk at very low levels of consumption⁵¹, or that high intakes of refined flour or sugar (rather than low intakes of fibre) increase risk through chronic hyperinsulinaemia or other mechanisms^{52,53}. At present, the hypothesis that fruits, vegetables and fibre may reduce the risk for colorectal cancer has not been firmly established.

Folate

Some recent prospective studies have suggested that a methyl-deplete diet (i.e. a diet low in folate and methionine and high in alcohol) is associated with an increased risk of colon cancer^{54,55}. Also, use of folic acid-containing multiple vitamin supplements has been associated with lower risk of colon cancer⁵⁶. A diminished folate status may contribute to carcinogenesis by alteration of gene expression and increased DNA damage^{57,58} and chromosome breakage⁵⁹. The finding that a common polymorphism in the methylenetetrahydrofolate reductase gene involved in folic acid metabolism may also be associated with colorectal cancer⁶⁰ strengthens the hypothesis that dietary folate may be an important factor in colorectal carcinogenesis.

Calcium

Another promising hypothesis is that relatively high intakes of calcium may reduce the risk for colorectal cancer, perhaps by forming complexes with secondary bile acids in the intestinal lumen³ or by inhibiting the hyperproliferative effects of dietary haem⁶¹. Several observational studies have supported this hypothesis^{3,4}, and two trials have suggested that supplemental calcium may have a modest protective effect on the recurrence of colorectal adenomas^{50,62}. More data are needed to evaluate this hypothesis.

Cancer of the liver

Liver cancer was estimated to account for 564,000 cases and 549,000 deaths in 2000¹¹. Approximately 75% of cases of liver cancer occur in developing countries, and liver cancer rates vary over 20-fold between countries, being much higher in sub-Saharan Africa and Southeast Asia than in Europe and North America⁷. The major risk factor for hepatocellular carcinoma, the main type of liver cancer, is chronic infection with hepatitis B, and to a lesser extent, hepatitis C virus⁶³. Ingestion of foods contaminated with the mycotoxin aflatoxin^{22,64} is an important risk factor among people in developing countries with active hepatitis virus infection. Excessive alcohol consumption is the main diet-related risk factor for liver cancer in Western countries, probably via the development of cirrhosis and alcoholic hepatitis⁶. Little is known about possible nutritional cofactors for viral carcinogenesis, but this may be an important area for research³.

Cancer of the pancreas

Cancer of the pancreas was estimated to account for 216,000 cases and 214,000 deaths in 2000 and is more common in Western countries than in developing countries^{7,11}. Time trends suggest that both incidence and mortality for cancer of the pancreas are increasing in most parts of the world, although some of this apparent increase may be due to improvements in diagnostic methods⁶. Overweight/obesity possibly increases the risk^{3,65}. Some studies have suggested that risk is increased by high intakes of meat, and reduced by high intakes of vegetables, but these data are not consistent and come mostly from case-control studies³. Over the next few years there will be substantially more prospective data on diet and cancer of the pancreas, and it is possible that more clear-cut associations with dietary factors will emerge.

Lung cancer

Lung cancer is the most common cancer in the world⁷ and was estimated to account for 1,239,000 cases and 1,103,000 deaths in 2000¹¹. Heavy smoking increases the risk by around 30-fold, and smoking causes over 80% of lung cancers in Western countries⁶. The possibility that diet might also have an effect on lung cancer risk was raised in the 1970s following the observation that, after allowing for smoking, increased lung cancer risk was associated with a low dietary intake of vitamin A⁶⁶. Since then, numerous observational studies have found that lung cancer patients generally report a lower intake of fruits, vegetables and related nutrients (such as β -carotene) than controls^{3,4}. The only one of these factors to have been tested in controlled trials, namely β -carotene, has however, failed to produce any benefit when given as a supplement for up to 12 years⁶⁷⁻⁶⁹.

The possible effect of diet on lung cancer risk remains controversial. Several recent observational studies have continued to observe an association of fruits and

vegetables with reduced risk, but this association has been weak in prospective studies^{70,71}. This apparent relationship may be partly due to residual confounding by smoking, since smokers generally consume less fruits and vegetables than non-smokers, but there may also be some protective effect of these foods. In public health terms, however, the overriding priority is to reduce the prevalence of smoking.

Breast cancer

Breast cancer is the second most common cancer in the world and the most common cancer among women. Breast cancer was estimated to account for 1,105,000 cases and 373,000 deaths in women in 2000¹¹. Incidence rates are about five times higher in Western countries than in less developed countries and Japan⁷. Much of this international variation is due to differences in established reproductive risk factors such as age at menarche, parity and age at births, and breastfeeding^{72,73}, but differences in dietary habits and physical activity may also contribute. In fact, age at menarche is partly determined by dietary factors, in that restricted dietary intake during childhood and adolescence leads to delayed menarche. Adult height, also, is weakly positively associated with risk, and is partly determined by dietary factors during childhood and adolescence⁷². Oestradiol and perhaps other hormones play a key role in the aetiology of breast cancer⁷², and it is possible that any further dietary effects on risk are mediated by hormonal mechanisms.

Overweight/obesity

Obesity increases breast cancer risk in postmenopausal women by around 50%, probably by increasing serum concentrations of free oestradiol⁷². Obesity does not increase risk among premenopausal women (perhaps because it frequently leads to anovular menstrual cycles), but obesity in premenopausal women is likely to lead to obesity throughout life and therefore to an eventual increase in breast cancer risk.

Alcohol

The only other established dietary risk factor for breast cancer is alcohol. There is now a large amount of data from well-designed studies which consistently shows a small increase in risk with increasing consumption, with about a 7% increase in risk for an average of one alcoholic drink every day⁷⁴. The mechanism for this association is not known, but may involve increases in oestrogen levels⁷⁵; alternatively, some recent studies suggest that the adverse effect of alcohol may be exacerbated by a low folate intake⁷⁶.

Fat

Much research and controversy has surrounded the hypothesis that a high fat intake increases breast cancer risk. The best data currently available, however, do not

support this hypothesis⁷⁷, and only limited data are available to evaluate whether dietary fat alters circulating oestrogen levels^{78,79}.

Other dietary factors

The results of studies of other dietary factors including meat, dairy products, fruits and vegetables, fibre and phyto-oestrogens are inconsistent^{3,4,80,81}.

Cancer of the endometrium

Endometrial cancer was estimated to account for 189,000 cases and 45,000 deaths in women in 2000, with the highest incidence rates occurring in Western countries^{7,11}. Endometrial cancer risk is about 3-fold higher in obese women than lean women^{15,82}. As with breast cancer, the effect of obesity in postmenopausal women on the risk for endometrial cancer is probably mediated by the increase in serum concentrations of oestradiol and the reduction in serum concentrations of sex hormone-binding globulin; in premenopausal women, the mechanism probably involves the increase in anovulation and consequent increased exposure to oestradiol unopposed by progesterone⁸³. Some case-control studies have suggested that diets high in fruits and vegetables may reduce risk and that diets high in saturated or total fat may increase risk, but the data are limited³.

Cancer of the cervix

Cancer of the cervix was estimated to account for 471,000 cases and 233,000 deaths in women in 2000¹¹. The highest rates are in sub-Saharan Africa, Central and South America, and south-east Asia⁷. The major cause of cervical cancer is infection with certain subtypes of the human papillomavirus⁸⁴. Fruits, vegetables and related nutrients such as carotenoids and folate tend to be inversely related with risk^{3,4}, but these associations may be largely due to confounding by papillomavirus infections, smoking and other factors. Further research is needed, particularly on the possible role of folate deficiency^{3,4}.

Cancer of the ovary

Cancer of the ovary was estimated to account for 192,000 cases and 114,000 deaths in women in 2000¹¹, with the highest incidence rates occurring in Western countries⁷. Risk is reduced by high parity and by long-term use of combined oral contraceptives⁸⁵. Some studies have suggested that risk is increased by high intakes of fat or dairy products, and reduced by high intakes of vegetables, but the data are not consistent and more prospective data are required to examine these possible associations³.

Prostate cancer

Prostate cancer was estimated to account for 543,000 cases and 204,000 deaths in 2000¹¹. Prostate cancer incidence rates are strongly affected by diagnostic practices and, therefore, difficult to interpret, but mortality

rates show that death from prostate cancer is about ten times more common in North America and Europe than in Asia⁷.

Little is known about the aetiology of prostate cancer, although ecological studies suggest that it is positively associated with a Western-style diet⁵. The data from prospective studies have not established causal or protective associations for specific nutrients or dietary factors^{3,4}. Diets high in red meat, dairy products and animal fat have frequently been implicated in the development of prostate cancer, although the data are not entirely consistent^{3,86–88}. Randomised controlled trials have provided substantial, consistent evidence that supplements of β -carotene do not alter the risk for prostate cancer^{67,68,89} but have suggested that vitamin E⁸⁹ and selenium⁹⁰ might have a protective effect. Lycopene, primarily from tomatoes, has been associated with a reduced risk in some observational studies, but the data are not consistent⁹¹.

Hormones control the growth of the prostate, and interventions that lower androgen levels are moderately effective in treating this disease. Prospective studies which have examined the possible associations between serum hormone concentrations and prostate cancer risk have suggested that risk may be increased by high levels of bioavailable androgens^{92,93} and of insulin-like growth factor-I (IGF-I)^{94,95}, although there are not sufficient data to consider either of these associations as established. Diet might affect prostate cancer risk by affecting hormone levels, and recent data suggest that animal protein may increase levels of IGF-I^{96,97}.

Bladder cancer

Cancer of the urinary bladder was estimated to account for 336,000 cases and 132,000 deaths in 2000¹¹. The geographic variation in incidence is about 10-fold, with relatively high rates in Western countries⁷. Smoking increases the risk for bladder cancer⁶. Studies suggest that high intakes of fruits and vegetables may reduce risk, but this is not established and more prospective data are needed^{3,98,99}.

Kidney cancer

Cancer of the kidney was estimated to account for 189,000 cases and 91,000 deaths in 2000¹¹. The range of geographic variation in incidence is moderate, with the highest incidence in Scandinavia and among the Inuit⁶. Overweight/obesity is an established risk factor for cancer of the kidney, and may account for up to 30% of kidney cancers in both men and women¹⁰⁰. There are only limited data on the possible role of diet in the aetiology of kidney cancer, but some studies have observed an increase in risk with high intakes of meat and dairy products and a reduced risk with high intakes of vegetables³.

Conclusions on the effects of diet on cancer risk

Strengths and weaknesses of the evidence

Attaining definitive evidence to confirm or refute effects of specific dietary factors on risks of human cancers is challenging and for many relationships may be impossible⁹. Ideally, each potential relationship would be tested in multiple randomised trials to achieve a clear conclusion. However, this is not feasible for many reasons, including the large number of dietary constituents that could be tested and the many different human cancers. In addition, uncertainty about the time in life and number of years before diagnosis that a specific aspect of diet may act hinders the design and interpretation of randomised trials. Practical problems with compliance in long-term studies and the need for many thousands of subjects create further obstacles. Finally, many dietary factors may not act in isolation and it may be their interaction with other dietary, lifestyle and/or genetic factors that may alter cell growth and affect cancer risk. For these and other reasons, randomised trials have contributed only modestly to present knowledge about diet and cancer, and this is likely to continue to be true for many years to come.

The primary alternative to randomised trials is observational studies of human cancers or their precursors, interpreted in the light of other evidence including metabolic studies, animal experiments and mechanistic investigations. Studies comparing rates of cancer in various populations and among migrants have been of prime importance in documenting the major role of environmental factors in the aetiology of nearly all major human cancers. However, from the beginning, epidemiologists have recognised that firm conclusions about specific aetiological factors cannot be based on comparisons of cancer rates among countries due to potential confounding by the multitude of lifestyle and other environmental factors that vary geographically. Case-control and prospective cohort studies within countries can provide better control of potential confounding variables, because these factors usually vary less within a geographic region and they can be measured and controlled for in statistical analyses. Until the last few years, case-control studies provided the large majority of data on diet and cancer. Concerns have existed that methodological biases, related to both the selection of study participants and the recall of diet after the diagnosis of cancer, could in some circumstances seriously distort the results of case-control studies. Now that a number of prospective studies are providing data on diet and cancer incidence, these concerns about the potential for bias in case-control studies have been supported because different results have often been observed, even within the same study population^{8,9}. At the time of the 1997 WCRF/AICR review³ it was recognised that associations between dietary fat and risk of breast cancer seen in case-control studies had not been confirmed in prospective studies with substantial

statistical power. Similar differences in results have now been observed for fat intake in relation to incidence of colon and lung cancers. A major conclusion of the 1997 review was that a greater intake of fruits and vegetables would substantially reduce risks of a broad range of cancers and decrease total cancer incidence by approximately 20%. However, most of the evidence was derived from case-control studies and, again, prospective studies have often found no or only weak support for the earlier findings. In particular, prospective studies have not supported earlier suggestions for strong inverse associations between overall intakes of fruits and vegetables and risks of lung and colon cancer, and little relation has been observed with breast cancer. Because rates of oral and oesophageal cancer are low in affluent populations, these have not been adequately evaluated in prospective studies. Thus, conclusions regarding protective effects of fruits and vegetables for these cancer sites should be viewed with some caution until confirmed in prospective studies.

Although prospective cohort studies will often provide the best available evidence regarding diet and cancer relationships, like any study they also have potential limitations that should be considered in the interpretation of findings. As in almost all dietary studies, only a part of the range of possible human intakes can be investigated. Thus, conclusions need to be limited to the range of diets investigated, in part because dose–response relationships may be non-linear. As with randomised trials, conclusions about findings need to be limited to the period in life or interval between dietary assessment and cancer diagnosis that was studied. Adequate precision in measurement of dietary intakes is necessary to detect true associations; the extensive literature on validity of dietary questionnaires, and the ability of current dietary assessment methods to

predict cardiovascular disease incidence, strongly suggest that major associations between dietary factors and cancer risk can be detected. In addition, prospective studies offer the opportunity for repeated measurements of dietary intake, which can reduce the error in measurement of long-term diet. However, because dietary assessments are inevitably imperfect and the size of study populations is finite, modest but still potentially important associations are usually impossible to exclude entirely. For some specific dietary factors, biochemical measurements can improve assessments of intake, but for many aspects of diet such measurements do not exist or enhance precision. A fundamental challenge in nutritional epidemiology is that foods are complex combinations of thousands of chemical constituents, thus isolation of the active factors can be difficult or impossible. For this reason, conclusions will be most reliable for foods or food groups, although data on supplement use can assist in evaluating hypotheses related to specific nutrients. Because dietary behaviours are often associated with other aspects of lifestyle that could affect cancer risk, studies also need to be evaluated for the degree to which confounding by such variables has been addressed.

Because all forms of studies have constraints, in most situations no single form of evidence will provide definitive conclusions regarding diet and cancer relationships. Thus, the best conclusions will be based on careful and critical evaluation of all forms of evidence.

Summary of the evidence for dietary factors and human cancer

Dietary components that we believe to be convincingly or probably related to the incidence of specific cancers are summarised in Table 1, together with other dietary factors

Table 1 Diet, nutrition and cancer: levels of evidence

Level of evidence	Decrease risk	Increase risk
Convincing	Physical activity (colon)	Overweight and obesity (oesophagus, colorectum, breast in postmenopausal women, endometrium, kidney) Alcohol (oral cavity, pharynx, larynx, oesophagus, liver, breast) Aflatoxin (liver) Chinese-style salted fish (nasopharynx)
Probable	Fruits and vegetables (oral cavity, oesophagus, stomach, colorectum*) Physical activity (breast)	Preserved meat and red meat (colorectum) Salt preserved foods and salt (stomach) Very hot (thermally) drinks and food (oral cavity, pharynx, oesophagus)
Insufficient	Fibre, soya, fish, <i>n</i> -3 fatty acids, carotenoids, vitamins B ₂ , B ₆ , folate, B ₁₂ , C, D, E, calcium, zinc, selenium, non-nutrient plant constituents (e.g. allium compounds, flavonoids, isoflavones, lignans)	Animal fats, heterocyclic amines, polycyclic aromatic hydrocarbons, nitrosamines

*A protective effect of fruit and vegetable intake has been suggested by many case-control studies but has not been supported in several large prospective studies, suggesting that if a benefit does exist it is likely to be modest.

which were considered to be possibly related to cancer risk but for which the evidence was considered insufficient. Physical activity is also listed in Table 1 because it is related to energy balance and overweight/obesity; a full discussion of the effects of physical activity on cancer risk is outside the scope of this paper, therefore, we have based our evaluation on the conclusions in the IARC Handbook on Weight Control and Physical Activity¹⁰¹.

Dietary factors which convincingly increase risk

Overweight/obesity

The nutritional factor for which the evidence was considered most convincing, and for which the quantitative impact on overall cancer rates is most important in populations with Western cancer incidence patterns, is overweight/obesity. Overweight/obesity is convincingly related to risks for cancers of the oesophagus (adenocarcinoma), colorectum, breast (postmenopausal), endometrium and kidney. Importantly, excess risk of these cancers increases continuously with greater adiposity and is not limited to clinical obesity (BMI over 30 kg/m²). The large increases in endogenous estrogen levels caused by excess body fat among postmenopausal women probably explain the higher risks of postmenopausal breast and endometrial cancer. The mechanisms for other cancers are less clear, but it has been suggested that hyperinsulinaemia may increase the risk for colon cancer^{52,102}. The WHO/IARC working group on weight control and physical activity estimated that in countries with high rates of cancers related to overweight, excess body weight (BMI over 25 kg/m²) accounts for approximately 39% of endometrial, 25% of kidney, 11% of colon, 9% of postmenopausal breast cancer and 5% of total cancer incidence^{82,101}. Although these percentages will be lower in populations in some developing countries where virally related cancers are more important, the rapid increase in overweight/obesity in developing countries means that cancers due to overweight/obesity will become increasingly important world-wide.

We recognise that overweight/obesity, a reflection of excessive energy intake, can result from both overconsumption of energy from food and low expenditure of energy as physical activity; the relative importance of these two factors can vary among individuals and populations. Considerable attention has been given to the possibility that the composition of the diet influences the probability of body fat accumulation and thus, indirectly, risk of cancer. Although the percentage of energy from dietary fat has been hypothesised to be an important determinant of body fat and the topic has been controversial, an important effect of dietary fat has not been supported in randomised trials lasting 1 year or more, and populations consuming low fat/high carbohydrate diets can clearly develop high rates of obesity¹⁰³. Other dietary factors that

may potentially influence the accumulation of body fat include high consumption of refined carbohydrate, highly energy-dense food (i.e. high energy content relative to volume or weight of food), and low fibre intake. However, evidence based on long-term studies for these effects of dietary composition is inadequate at present. Thus, at this time the appropriate emphasis for weight control appears to be limitation of excessive energy intake from any source and the adoption of adequate daily physical activity.

Alcoholic beverages

Another aspect of diet clearly related to cancer incidence is consumption of alcoholic beverages, which convincingly increases the risk of cancers of the oral cavity, pharynx, larynx, oesophagus, liver and breast (and probably colorectum). The increase in risk appears to be primarily due to alcohol *per se* rather than specific alcoholic beverages. Whereas most of the excess risks occurs with high alcohol consumption, a small (about 7%) increase in risk of breast cancer has been observed with approximately one drink per day. Recent studies suggest that the excess risk of breast and colon cancer associated with alcohol consumption may be concentrated in persons with low folate intake.

Aflatoxin

Food contaminated with aflatoxin convincingly increases the risk of liver cancer. However, this contamination occurs mainly in areas where hepatitis viruses are a major cause of liver cancer, and the importance of aflatoxin in the absence of hepatitis virus infections (for example, after immunisation) is not clear.

Chinese-style salted fish

High intake of Chinese-style salted fish, predominantly consumed in some Asian populations, convincingly increases the risk of nasopharyngeal cancer.

Dietary factors which probably reduce risk

Fruits and vegetables

Overall, a high intake of fruits and vegetables probably reduces the risks of cancers of the oral cavity, oesophagus, stomach and colorectum. Previous reviews of diet and cancer, including the 1997 WCRF/AICR review, have given greater emphasis to increasing fruit and vegetable consumption for cancer prevention, and have included cancers of the larynx, lung, pancreas, breast and bladder. At that time, however, the available literature was based largely on case-control studies, and subsequent prospective studies have not supported important protective effects for cancers of the lung and breast, and have suggested that the reduction in risk for colorectal cancer may be modest. These discordant results, which add to concerns about the potential for bias in case-control studies, also suggest the need for some caution regarding

conclusions about intake of fruits and vegetables and the risks of oral, oesophageal and stomach cancers, which have not been adequately examined in large prospective studies. Furthermore, none of the dietary studies of stomach cancer has controlled adequately for infection by *H. pylori*, which is a potential confounding variable.

Although support for a broad and strong protective effect of higher fruit and vegetable intake against cancer incidence has weakened with the results from recent studies, modest benefits of increasing fruit and vegetable intake have not been excluded and probably do exist. The issue of dose–response is important, and some evidence suggests that a very low intake of fruits and vegetables, e.g. less than 2 servings or 200 g/d, is related to increases in risk compared with higher intakes, but that there may be little additional benefit for intakes higher than about 400 g/d^{51,81}. Also, fruits and vegetables are extremely heterogeneous, and it is possible that only specific foods are related to risk for specific cancers. As examples, some studies have suggested that intake of tomato products, high in lycopene¹⁰⁴, is inversely related to risk of prostate cancer and that cruciferous vegetable intake is inversely associated with bladder cancer incidence⁹⁹. In these same studies, overall fruit and vegetable consumption was not associated with cancer risk. Should this be considered as general support for a protective effect of fruits and vegetables, or only for more specific relationships? Another complexity can arise when a micronutrient in the form of a supplement is shown to be related to cancer risk. This might be construed as evidence that fruits and vegetables containing this factor are protective against cancer. However, this does not necessarily follow because bioavailability of micronutrients in fruits and vegetables might be low or antagonistic factors might be present. Folate may provide such an example as there is now considerable evidence that higher intake, mainly due to use of multiple vitamins, may be related to lower risks of colorectal and breast cancers. Also, in this situation, use of supplements and fortified foods could mask a beneficial effect of fruits and vegetables if folate were an important protective component of these foods.

Preserved meat and red meat

In many studies, high intakes of preserved meat or red meat have been associated with increased risk of colorectal cancer, whereas the total fat content of the diet does not appear to be related to risk. The components of preserved and red meat that might increase colorectal cancer risk are not established; heterocyclic amines created by cooking, haeme iron, and specific fatty acids have been proposed as explanations.

Salt preserved foods and salt

High intakes of salt-preserved foods and of salt probably increases the risk of stomach cancer. Convincing evidence would require confirmation in prospective studies and

evidence that this relationship was not confounded by *H. pylori* infection. Notably, stomach cancer rates in the US are now very low even though salt intake is not.

Very hot drinks and foods

Consumption of very hot drinks and foods typically consumed in some cultures probably increases risk of cancers of the oral cavity, pharynx and oesophagus.

Cancers not included in table

For cancers of the pancreas, lung, cervix and ovary, we did not consider these to be convincing or probable evidence of a dietary relationship. In earlier reviews, evidence had been considered stronger for a protective effect of fruit and vegetable consumption against lung cancer risk. However, more recent prospective studies have found weaker associations, and residual confounding by cigarette smoking remains a concern. Although a weak relation with fruit and vegetable intake is possible, avoidance of smoking is the only effective way to substantially reduce lung cancer rates.

Diets very high in starch and low in overall micronutrient intake, consumed by poor populations in many countries, have been associated with increased risks of oral and oesophageal cancers. Isolation of the specific micronutrients responsible has been elusive, but an overall improvement of these poverty-related diets is clearly warranted for health in general.

Conclusions on dietary factors and cancer

Since the 1981 Doll and Peto review on diet and cancer mortality¹, about one third of cancers have generally been thought to be related to dietary factors. More recent evidence suggests that this number may be too high, but a revised quantitative estimate is beyond the scope of this review. Among the diet-related factors, overweight/obesity convincingly increases the risks of several common cancers. After tobacco, overweight/obesity appears to be the most important avoidable cause of cancer in populations with Western patterns of cancer incidence. Among non-smoking individuals in these populations, avoidance of overweight is the most important strategy for cancer prevention.

Policy implications

Public health policy with respect to nutrition and cancer should be based on the best available scientific research. In the previous section, we concluded that few dietary effects on cancer risk have been established. Avoiding overweight/obesity, limiting alcohol intake and increasing physical activity will reduce cancer risk, as will limiting consumption of Chinese-style salted fish and minimising dietary exposure to aflatoxin in populations where these dietary factors are important. Risk will probably be decreased by increasing the average intake of fruits and

Table 2 Diet, nutrition and cancer: recommendations

1.	Maintain BMI in range of 18.5–25 kg/m ² , and avoid weight gain in adulthood
2.	Engage in regular physical activity
3.	Consumption of alcoholic beverages is not recommended: if consumed, do not exceed 2 units/d (1 unit is equivalent to approximately 10 g of alcohol and is provided by one glass of beer, wine or spirits)
4.	Minimise exposure to aflatoxin in foods
5.	Chinese-style salted fish should only be eaten in moderation, especially during childhood. Overall consumption of salt-preserved foods and salt should be moderate
6.	Have a diet which includes at least 400 g/d of total fruit and vegetables
7.	Meat: those who are not vegetarian are advised to moderate consumption of preserved meat (e.g. sausages, salami, bacon, ham etc.) and red meat (e.g. beef, pork, lamb). Poultry and fish (except Chinese-style salted fish, see 5. above) have been studied and found not to be associated with increased cancer risk
8.	Do not consume foods or drinks when they are at a very hot (scalding hot) temperature

vegetables, and by limiting intake of preserved and red meat, salt preserved foods and salt, and very hot drinks and food. Public health policy should, therefore, be focussed on these factors (Table 2). If other dietary factors are established to affect cancer risk then these can be added to existing policy frameworks, but at present the other potentially important dietary factors are not sufficiently well supported by evidence, and including them in policy would risk confusing priorities and diverting attention from the really important issues.

Acknowledgements

An earlier version of this paper was prepared as a background paper for the Joint WHO/FAO Expert Consultation on diet, nutrition and the prevention of chronic diseases (Geneva, 28 January–1 February 2002). The authors wish to thank Professor Tony McMichael, National Centre for Epidemiology and Population Health, Australia National University, Canberra, Australia, Dr Larry N. Kolonel, Cancer Research Center of Hawaii, University of Hawaii, Honolulu, USA, Dr Shaw Watanabe, Department of Nutrition and Epidemiology, Tokyo University of Agriculture, Tokyo, Japan, and Dr Shoichiro Tsugane, Epidemiology & Biostatistics Division, National Cancer Center Research Institute, Kashiwa-City, Japan, for their thoughtful and constructive comments on the earlier

manuscript. The authors are particularly thankful to Dr Elio Riboli, International Agency for Research on Cancer (IARC), Lyon, France, for his valuable help and contributions during the drafting of the manuscript.

Note added in press—acrylamide

Acrylamide is a chemical classified by the International Agency for Research on Cancer as a probable human carcinogen¹. This classification is based on experiments in rats and mice, which show that high doses of acrylamide increase the risk for several cancers, including cancers of the lung, mammary gland, thyroid and oral cavity. In 2002, a

Swedish food survey reported that common foods such as fried potatoes, potato crisps (chips), bread and breakfast cereals contain moderately high levels of acrylamide². Subsequent studies showed that acrylamide is generated when the amino acid asparagine is heated above 100°C in the presence of sugars; potatoes and cereals are both rich in asparagine^{3,4}. Moderate acrylamide levels in common foods have now been reported from several countries, and these findings have raised concern that dietary acrylamide may increase cancer risk in humans⁵. The intake of acrylamide from food may be several hundred-fold lower than the lowest dose at which adverse effects have been observed in rats⁶, and at the time of writing (January 2003) the only information concerning cancer risk in humans comes from a case-control study in Sweden⁷. This study estimated acrylamide intake from the reported intake of 10 foods, and observed no evidence that increasing intake of food sources of acrylamide was associated with the risk for cancers of the colorectum, kidney or bladder. Although these first results are moderately reassuring, more data are urgently needed from studies using questionnaires validated for estimating acrylamide intake, or biomarkers of acrylamide exposure.
